Basic concepts of Current-mode logic

1. Fast operation speed
   - □ Reduced RC time constant
2. To maintain the low swing output
   - □ Current-mode logic inherently enables low swing operation.
   - □ For voltage-mode logic: reset operation is required.
3. To reduce the noise effect

(a)

(b)

$$\tau_a = r_1 c_1$$

1.

$$\tau_b = \frac{r_2}{r_1 + r_2} r_1 c_1$$

2.

$$V_{1b} = \frac{r_2}{r_1 + r_2} V_{in}$$
3. Immunity of noise in current-mode logic

■ Current-mode loop in steady state can be approximated by a resistor loop.

■ Node a1 has voltage V1, which is subjected to a noise ΔV.

  □ Noise in high-branch:

  $$\frac{\Delta V_{rs}}{\Delta V} = \frac{r_s}{r_{total} - r_1}$$

  □ Noise in low-branch:

 $$\frac{\Delta V_{rs}}{\Delta V} = -\frac{r_s}{r_{total} - r_1}$$

Design rules for CMDL

- The internal and output nodes are low swing, and the output must be greater than 0.1v (For Vdd=1.0v)
  - To guarantee the low swing outputs:
    - For any input pattern, the differential inputs must be connected through a shunt resistor or a closed transistor.
  - To guarantee the differential output is larger than 0.1v:
    - For each pair of differential output, there shall be no other shunt resistors or close transistors on the active path.
- The DCN can have multiple inputs and multiple outputs.
- Any path from the input to output has at most six stages of logic.
